Working Paper No. 15

December 2016
Adjudication: Type-I and Type-II Errors*

Matteo Rizzolli†

October 29, 2016

Abstract

Adjudicative procedures meant at establishing truth about facts on defendants’ behavior are naturally prone to errors: defendants can be found guilty/liable when they truly were not (type-I errors) or they can be acquitted when they should have been convicted (type-II errors). These errors alter the incentives of defendants to comply with norms. We review the literature with a particular focus on type-I errors.

Keywords: type-I errors, wrongful convictions; justice concerns, burden of proof, deterrence; law enforcement

JEL Code: K4

1 Introduction

The word *adjudication* has its Latin roots into the words *jus* (right, justice) and *dicere* (to say). All organizations set goals and have adjudicative procedures to “establish the truth” about members’ compliance. Performance appraisal committees decide whether employees earn rewards within business organizations; teachers must assess students progress in learning; courts adjudicate whether citizens have committed crimes; disciplinary committees within sport leagues and professional organizations as well as religious tribunals assess whether members’ conduct has been conforming. Adjudicative procedures must evaluate and reward something they cannot directly observe—being it effort, intention or act—and this makes them obviously prone to errors. Although our framing will be mostly applied to criminal, administrative and civil courts, most of the results here presented apply to any generic adjudicative procedure. We thus consider the general case of an adjudicative authority who i) must assess whether the observed behavior of an individual conforms or deviates from the prescribed behavior and ii) must incentivize or sanction such behavior accordingly. In judging behavior errors inevitably arise and they generally undermine individuals incentives. These errors take mainly two forms: i) the adjudicative authority may assess non-compliance when in fact the subject is duly complying (this is defined as a type-I error\(^1\)) and ii) the adjudicative authority may assess compliance when in fact the subject is deviating (this is a Type-II error). In the context of crime deterrence type-I errors amount to wrongful convictions of innocents. We model the relation between type-I and type-II errors below within a standard optimal deterrence framework. Finally we discuss the empirical relevance of type-I errors.

Basic setup

Let \( y_0 \) be the initial endowment equal for all agents and \( b \) the benefits from deviating from the prescribed behavior (e.g. committing crime). \( b \) is distributed among the agents with a generic distribution \( z(b) \) and a cumulative \( Z(b) \) with support \([0, B]\). Let also \( h \) be the harm/externality generated by each individual’s deviation\(^2\) (each individual takes this decision only once). For the sake of simplicity, all individuals are audited and brought in front of an adjudicative authority\(^3\). The authority observes the amount of inculpatory evidence \( e \) that is produced against a defendant and if this overcomes a certain threshold \( \tilde{e} \) then the authority imposes a monetary sanction \( s \). For the sake of simplicity, we also assume that there is no welfare-improving deviation as in Becker (1968) (this would be a crime for which \( b > h \)) and that monetary sanctions are transferred from the defendant to society. Furthermore, in the function of social costs we do not consider the private benefits from crime but only its social costs\(^4\).

---

\(^1\)Individual’s compliance with the prescribed behavior can be interpreted as the null hypothesis, so that the adjudicative authority can both incorrectly reject the null and sanction a complying subject (a Type-I error) and incorrectly accept the null and exculpate an undeserving subject (Type-II error).)

\(^2\)One can think of this crime has having no specific victim but the harm is inflicted upon the society as a whole. An example of such a victimless crime is insider trading.

\(^3\)Adding here a police agency that could detect crime with some \( p \) probability of detection would not change the results as long as the detection is random. For more complex technologies of detection see Mookherjee and Png (1992); Kaplow (2011).

\(^4\)Whether private benefits of crimes should be computed in the social welfare function is the subject of a long-lasting debate. See Rizzolli and Saraceno (2013)
Therefore let \( e \) have a frequency distribution of \( i(e) \) for the conforming defendant (innocent) and of \( g(e) \) for the deviating defendant (guilty). Let \( I(e) \) and \( G(e) \) be the cumulative distributions of \( i(e) \) and \( g(e) \) respectively and note that \( I(\tilde{e}) \) and \( G(\tilde{e}) \) are the probabilities of being acquitted for the complying and for the deviating defendant respectively, given the evidence threshold \( \tilde{e} \). To keep notation compact we will often use \( I,G \) for \( I(\tilde{e}), G(\tilde{e}) \) respectively.

The evidence is stochastically distributed, albeit in general more incriminating evidence is available against deviating defendants than against complying ones\(^5\). Note also that \( G \) is the probability of type-II error and \( 1-I \) is the probability of type-I error. Let us also define \( \Delta(\tilde{e}) = I - G \) as the accuracy of the adjudicative procedure; \( \Delta \) represents the ability of the procedure to distinguish complying from deviating defendants.

For our purpose we assume the social planner optimizes deterrence only by affecting the threshold \( \tilde{e} \) which in turn determines the error’s tradeoffs: for instance an increase in \( \tilde{e} \) generates both an increase in the number of wrongful acquittals \( G \) and a decrease in the number of wrongful convictions \( 1-I \).

The risk-neutral individual does not deviate as long as the returns from deviating behavior are smaller than the expected returns of conforming. Since \( \tilde{e} \) varies across individuals, there exist a level of \( \tilde{b} \) for which the individual is indifferent between conforming or not and this determines the proportion of the population \( Z(\tilde{b}) \) who conforms.

Social welfare is thus \((1-Z(\tilde{b}))h):\) the social costs of harm caused by those defendants who deviate. On the other hand the social planner only acts on the threshold \( \tilde{e} \) which implicitly defines the tradeoff between type-I and and type-II errors. The link between the social planner’s choice of the evidentiary standard \( \tilde{e} \) which in turn determine the error’s tradeoff and the defendant choice of conformity determined in \( \tilde{b} \) are the ingredients to understand the role of adjudication in deterrence.

Let us begin by assuming agents to be risk-neutral utility maximizers. The returns from conforming are \( E\pi_I = y_0 - (1 - I)s \) while the returns from deviating are \( E\pi_G = y_0 + b - (1 - G)s \). All defendants for which \( E\pi_I \geq E\pi_G \) will conform and therefore the threshold level of \( b \) which implicitly defines the conforming population is \( \tilde{b}_{rn} = (1 - (1 - I) - G) s \)

By looking at Equation 1, we can single out the typical “deterrence effect” (Becker, 1968) as \( \tilde{b} \) increases both with the magnitude of the sanction (\( \uparrow s \Rightarrow \uparrow \tilde{b} \)) and via an increase in the detection probability for the deviating defendants which in this model corresponds to a decrease in the probability of type-II errors (\( \downarrow G \Rightarrow \uparrow \tilde{b} \)). Furthermore a “compliance effect” of type-I errors can be seen: \( s \tilde{b} \) increases when the probability of being punished decreases for conforming defendants (\( \uparrow I \Rightarrow \uparrow \tilde{b} \)).

Also a “screening effect” can be established: the higher is the accuracy \( \Delta \), the better the procedure can discriminate between conforming and non conforming behavior, the greater the advantages of staying conforming (\( \uparrow \Delta \Rightarrow \uparrow \tilde{b} \)). Finally, by simple inspection of 1, it is evident that marginal change in either \( 1-I \) or \( G \) determines an equal decrease of \( \tilde{b} \) as \( \frac{\partial b}{\partial (1-I)} = \frac{\partial b}{\partial G} = s \). Under risk neutrality, type-I errors \((1-I)\) and type-II errors \((G)\) have the same negative impact on the defendant’s incentive to comply. This is because on one hand type-II errors undermine compliance inasmuch as they decrease

---

\(^5\)First order stochastic dominance is assumed \( I(e) > G(e) \) \( \forall e \in [0,e_{max}] \). Without FOSD evidence would be produced randomly for the complying and the deviating alike and therefore the whole criminal procedure would be pointless.
the probability of non-conforming defendants being finally sanctioned. On the other hand type-I errors
increase the opportunity costs of conforming relative to deviating.

Now that the threshold level \( \tilde{b} \) is defined, the social welfare can be computed and derived with
respect to the evidence threshold

\[
\frac{\partial SW}{\partial e} = \partial \left( 1 - Z(\tilde{b}_{rn}) \right) h = -z(\tilde{b}_{rn}) (i(\tilde{e}) - g(\tilde{e})) s h
\]

(2)

Let \( \tilde{e}_{neutral} \) be implicitly defined by \( i(\tilde{e}) = g(\tilde{e}) \). By inspection of equation 2 the optimal evidence
threshold \( \tilde{e} \) that minimizes social costs is \( \tilde{e}_{neutral} \). In fact accuracy reaches its maximum level when the
social planner chooses \( \tilde{e}_{neutral} \) so that the distance between the two cumulative functions is maximized.

Evidence thresholds, Standard of Evidence and Error Ratios

While our analysis focuses on the evidentiary threshold \( \tilde{e} \) that determines the probabilities of both
type-I and type-II errors, there are other two common concepts that concern adjudication and that
must be put in relation with our analysis.

The first one is the **Standard of Evidence**: it is generally understood as the level of certainty the
adjudicative authority must reach in order to establish guilt in a criminal proceeding (or liability in
civil one). Among the most common standards of proof used in different adjudicative procedures there
are the *preponderance of evidence (poe)* standard; the *clear and convincing evidence (cace)* standard,
and the *beyond any reasonable doubt (bard)* standard. Although giving probabilistic interpretations of
these standards of proof is very controversial (see Kaplow, 2012, footnote 76 for a discussion) they are
commonly understood to roughly coincide with the 50%, 75% and 95% thresholds respectively. Under
*poe* (or *cace* or *bard*), the adjudicative authority must answer to the question of whether, given the
evidence available, the likelihood that the defendant has deviated is larger than 50% (or 75% or 95%
depending on the standard applied). These probabilities must be understood as Bayesian posterior
probabilities of having deviated and these are functions -following the Bayes’ rule- of the likelihood of
the signal given by the densities \( i \) and \( g \) of the evidentiary threshold \( \tilde{e} \) and on the prior probability of
being brought in front of the adjudicative authority. The probability that a defendant has deviated or
not also depends on the base rates of the two actions: \( (1 - Z(\tilde{b})) \) and \( (Z(\tilde{b})) \) respectively. The \( \tilde{b} \)
are determined endogenously by defendants’ decisions and ultimately depend on the evidence threshold
\( \tilde{e} \). Therefore in order to identify the proper threshold \( \tilde{e} \) -in case the *poe* standard applies- one should
ask what value of \( \tilde{e} \) implicitly solves the equation \( g(\tilde{e}) \cdot (1 - Z(\tilde{b})) = i(\tilde{e}) \cdot Z(\tilde{b}) \). If the adjudicative
authority needs to apply the *cace* or *bard* standard one could simply multiply by either 3 or 19 the
right side of the previous equation. As Lando (2002); Kaplow (2012) points out, the two notions

\footnote{For instance, the *cace* standard amounting to a 75 percent likelihood implies that the threshold evidence \( \tilde{e} \) was three
times more likely to have been produced by a defendant who deviated than from one who has conformed.}
-the one based on the optimal evidence threshold and the one based on the standard of evidence- are strikingly different. To begin with, the optimal evidence threshold is derived from welfare analysis and seeks to find the level of \( \tilde{e} \) that maximizes social welfare. By contrast, within the standard of evidence framework, \( \tilde{e} \) is derived by asking under what circumstances would the probability that the defendant before the adjudicative authority has actually deviated be 50% (or 75% or 95% or other conventional probability). In fact the optimal evidence threshold could be associated with any probabilistic standard of evidence whatsoever\(^7\).

Another approach focuses on the ratio of errors and expresses the pro-defendant bias of adjudicative procedures in terms of errors ratios. There seem to be something specific about type-I errors in the context of crime: Volokh (1997) masterfully collected hundreds of quotes from scholars and rule-makers across time and societies advocating a specific attention to the avoidance of type-I errors even at the expenses of many type-II errors; arguably the most famous statement in this respect is the one of William Blackstone (1769) recommending that it is better that ten guilty persons escape than that one innocent suffer. Blackstone’s error thus fixes the acceptable ratio to 10, while Hale and Emlyn (1736) thought that 5 was more agreeable and Fortescue (1741) argued for 20 and so on. Dekay (1996) systematizes the relation between the standards of evidence and the errors ratios. We can interpret these as ratios of errors’ frequencies where the frequency of erroneous acquittals is the conditional probability that a truly deviating defendant is acquitted (type-II error) multiplied by the base rate of the action \((1 - Z(\tilde{b}))\) while the frequency of erroneous conviction is the conditional probability that a truly complying defendant is convicted (type-I) multiplied by the base rate \(Z(\tilde{b})\). So the type-I error ratio (sometimes also called the Blackstone’s error ratio) is defined as \(\frac{G \cdot (1 - Z(\tilde{b}))}{(1 - I) \cdot Z(\tilde{b})}\).

All else being equal, higher standards of evidence that affect the tradeoff between \(G\) and \(I\) do imply higher Blackstone-like error ratios. However it should be noticed that the optimal evidence threshold could be associated with many different error ratios depending on the base rates.

**Risk and Loss aversion**

Subjects are known to be generally risk-averse in their utility of income. We thus introduce risk-aversion in the measure of the monetary gains from crime \(b\) following (Rizzolli and Stanca, 2012). If \(b\) are monetary gains for which utility \(U(.)\) can be derived then the expected utility of complying is \(I \cdot U(y_0) + (1 - I) \cdot U(y_0 - s)\) while the expected utility of deviating is \(G \cdot U(y_0 + b) + (1 - G) \cdot U(y_0 + b - s)\). The threshold level of \(\tilde{b}_{eu}\) that triggers a defendant to deviate is implicitly defined by

\[
I [U(y_0) - U(y_0 - s)] - G [U(y_0 + b) - U(y_0 + b - s)] \geq U(y_0 + b - s) - U(y_0 - s) \quad (3)
\]

Equation 3 shows that when there is an increase in either of the errors (increase in \(G\) or decrease in \(I\) on the left-hand side of the equation, defendants find deviation convenient for lower levels of \(b\) on the right-hand side). However, given the concavity of the utility function, the negative impact of type-I errors \((1 - I)\) on the threshold level \(\tilde{b}_{eu}\), and thus on social welfare is stronger than that of type-II errors \((G)\). To see why, note that \(U(y_0) - U(y_0 - s) > U(y_0 + b) - U(y_0 + b - s)\). In order

\(^7\)See Kaplow, 2012 for discussion and numerical examples
to maintain the same level of deterrence, a given percentage increase of $1 - I$ must be compensated by a smaller percentage decrease of $G$. Therefore, assuming risk aversion, type-I errors $(1 - I)$ create more disutility and thus induce more deviation than comparable type-II errors $(G)$; therefore social costs are minimized for a $\tilde{e}^* > \tilde{e}_{\text{neutral}}$. The opposite result holds if we instead assume risk-seeking behavior.

Another interesting extension concerns the introduction of loss aversion: a departure from the expected utility framework that has been incorporated in models such as the Cumulative Prospect Theory (Tversky and Kahneman, 1992; Dhami and al Nowaihi, 2013) and Reference Dependent Preferences à-la Koszegi and Rabin (2007). These models build on the empirical observation that people tend to think of possible outcomes of a choice under uncertainty relative to a certain reference point and tend to prefer the avoidance of losses (outcomes below the reference point) than the acquisition of comparable gains (outcomes above the reference point). Incorporating reference dependent preferences and loss aversion in the model is not trivial (see Nicita and Rizzolli, 2014) however the intuition and the results are quite simple: type-I errors always imply a potential loss relative to the status quo while this is not necessarily true for type-II errors. To conclude, in presence of loss aversion, type-I errors $(1 - I)$ represent a net loss and impact the defendant value function more than comparable type-II errors $(G)$; therefore social costs are minimized for a $\tilde{e}^* > \tilde{e}_{\text{neutral}}$.

**Cost of sanctions**

So far we have assumed that the sanction $s$ is monetary and that it implies -once imposed- a costless transfer from the defendant to the society. However the imposition of sanctions imply both private costs of punishment to defendants and to society as well. Non-monetary sanctions are a social cost (Polinsky and Shavell, 1984; Shavell, 1987b) as their imposition imply a disutility for the defendant that is not transferred to society. Furthermore all sanctions -including monetary fines- must be administered and therefore imply a social cost (Polinsky and Shavell, 1992).

Define $c$ as the total cost (both to the defendant and to the society) of imposing a sanction. The social welfare function (assuming risk neutrality) should be rewritten as following

\[
SW = [1 - Z(\tilde{b})] h + [1 - Z(\tilde{b})] (1 - G) c + Z(\tilde{b}) (1 - I) c
\]  

The first term of the equation 4 represents the harm/externality of deviating, as before. The second term represents the expected total costs of imposing sanctions on deviating defendants and the third term represents the expected total costs of punishing complying defendant (type-I errors). The problem lies in defining the optimal $\tilde{e}$ that minimizes the expected total costs from crime, including the costs of punishment. As before, the first term is minimized for $\tilde{e} = \tilde{e}_{\text{neutral}}$. However the second and third terms are minimized for $\tilde{e} \rightarrow \infty$. In fact for an evidence threshold $\tilde{e}$ arbitrarily high, the probability of correctly imposing a sanction on a deviating defendant $(1 - G)$ or erroneously imposing a sanction on a complying defendant $(1 - I)$ decrease to zero and -since nobody is punished- there are no costs of punishment for society. When social costs are considered, the costs of harm implied by the first term must thus be balanced against the costs of punishment of the second and third term. Therefore in presence of costs of punishment the social costs of harm must be weighted against the social costs of
punishment and therefore social costs are minimized for $\tilde{e}^* > \tilde{e}_{\text{neutral}}$. This result is based on Kaplow (1994); Rizzolli and Saraceno (2013).

**Identity Errors**

Lando (2006) introduced a distinction between *mistakes of act* and *mistakes of identity*. *Mistakes of act* happen when an defendant is judged deviating when in fact he was complying. These are the adjudicative errors we have been focusing on so far, for which the main concern of the adjudicative authority is whether there actually was any deviation at all. Note that, in case of mistakes of act, the two errors are independent: an increase in wrongful convictions does not imply any change in the number of wrongful acquittals. Then there are *mistakes of identity*, by which in the presence of deviations that can be easily observed, such as a murder or a robbery in the context of crime, the wrong person can be incriminated for an act that actually did happen. These are the cases where the occurrence of the deviation cannot be denied and the authority is concerned with who committed the crime. Note that in this case the two errors for a given crime are linked, as the conviction of an innocent person implies the acquittal of the person actually responsible for it\(^8\).

Suppose that at time $t_1$ there exists an exogenous probability $\beta_{i,g}$ that an defendant is sanctioned for a deviation that has already happened at $t_0$ and which the subject is not responsible for (a mistake of identity). This exogenous probability can vary depending on the decision of the defendant at $t_1$: it seems reasonable to assume that abstaining from a crime at $t_1$ reduces the probability of a mistake of identity, so that $\beta_i \leq \beta_g$. Thus the returns from conforming at $t_1$ are $E\pi_I = y_0 - (1 - I)s - \beta_is$ while the returns from deviating are $E\pi_G = y_0 + b - (1 - G)s - \beta_gs$. The threshold level of $b$ which implicitly defines the conforming population is

$$\tilde{b}_{\text{identity}} = (1 - (1 - I) - G)s - (\beta_i - \beta_g)s$$

(5)

Inspection of 5 and comparison with equation 1 highlights the role of mistakes of identity vis-à-vis deterrence implicitly defined by $\tilde{b}_{\text{identity}}$. The first part is equal to equation 1 while, in the second part, if $\beta_i = \beta_g$ as Lando (2006) hypothesized, then identity errors occurred at $t_0$ have no impact on deterrence at $t_1$. However if $\beta_i < \beta_g$ then identity errors actually have a positive impact on deterrence. The reason is intuitive: the decision to deviate in $t_1$ triggers a net increase in the probability of being wrongfully convicted because of a mistake of identity. Of course this result is based on the assumption that the probability of identity errors in $t_1$ is determined exogenously and it is not a function of $\tilde{e}\(^9\)$. Furthermore, identity errors impose a necessarily constraint between the input of wrongful acquittals and the output of wrongful identity convictions; Garoupa and Rizzolli (2013) show that once this constraint is considered, mistakes of identity have a net negative impact on deterrence.

---

\(^8\)Note that the inverse causation does not necessarily hold, as the acquittal of the perpetrator does not imply the conviction of an innocent person.

\(^9\)This assumption could be justified on the ground that the conviction of the true culprit depends also on police and prosecution behavior and thus it might be exogenous to adjudication. See also Epps (2015).
Errors and the precaution of harm

Another main area where the role of adjudicative errors has been explored is tort law (see Png 1986; Shavell 1987a; Lando and Mungan 2014 among others). The standard model of tort law substitutes the dichotomous choice between complying and deviating with a continuous choice about the level of activity/care. We will discuss the main implications below. However some novel conclusions can be drawn also from applying the dichotomous choice model. In this framework the defendant chooses between conforming to the prescribed standard of care or deviating and not taking any precaution. Since taking precautions is costly we can interpret $b$ as the opportunity cost of conforming (by deviating the defendant saves $b$). Furthermore the sanction is equal to the harm inflicted since the goal of the tort system is compensation, and the decision to conform only reduces the expected harm $10$: when conforming, harm $h_i$ is produced with probability $\alpha_i$ while, when deviating, harm $h_g$ is produced with probability $\alpha_g$, where $h_g > h_i$ and $\alpha_g > \alpha_i$. Adjudicative errors can occur in the usual way and therefore, a risk-neutral defendant’s returns from conforming are $E\pi_I = y_0 - (1 - I)\alpha_i h_i$ while the returns from deviating are $E\pi_G = y_0 + b - (1 - G)\alpha_g h_g$. All defendants for which $E\pi_I \geq E\pi_G$ will conform and therefore the threshold level of $b$ which implicitly defines the conforming population is

$$\tilde{b}_{\text{care}} = (1 - G) \cdot \alpha_g h_g - (1 - I) \cdot \alpha_i h_i$$  \hspace{1cm} (6)$$

By comparing equation 6 with 1 one immediately realizes that type-I errors have a smaller impact on the incentive to comply than type-II errors as $\frac{\partial b}{\partial (1 - I)} = \alpha_i h_i < \frac{\partial b}{\partial G} = \alpha_g h_g$; this is because complying causes a smaller expected harm. Also social welfare changes as now also complying defendant cause harm. To find out the optimal $\tilde{e}$ we compute $\frac{\partial SW}{\partial e} = 0$ and thus

$$\partial Z(\tilde{b}) \alpha_i h_i + \partial (1 - Z(\tilde{b})) \alpha_g h_g = (\alpha_i h_i \tilde{e} - \alpha_g h_g \tilde{e}) (\alpha_i h_i - \alpha_g h_g) = 0$$  \hspace{1cm} (7)$$

Rearranging 7 we have that $i(\tilde{e}) = \frac{\alpha_i h_i}{\alpha_i h_i - \alpha_g h_g} \tilde{e}$ and since $\frac{\alpha_i h_i}{\alpha_i h_i - \alpha_g h_g} > 1$ the equality can be satisfied only for $\tilde{e}^* < \tilde{e}_{\text{neutral}}$. We can thus conclude that when defendants face a dichotomous choice between complying and causing a smaller expected harm or deviating and causing a larger expected harm, type-I errors impact deterrence less than type-II errors and therefore welfare is maximized for a level of evidentiary standard smaller than the neutral one.

Precautionary activities and chilling of desirable behavior

In both the crime and the tort context, the choice of deviating causes social harm at least in expected terms$^{11}$. In many situations however defendant compliance can have both harmful consequences as well as benign ones. One may think of the case of competition policy, where the threat of antitrust sanctions may discourage efficient, pro-competitive behavior; another case may be medical malpractice, where worries about false positives may prevent cost-effective care$^{12}$. Kaplow (2011) model envisages a population that can engage in an harmful act that produces a private benefit as well as a negative

---

10 whereas in the crime-like setup conforming prevents all harm
11 compliance instead causes no harm in the crime context while it produces a smaller social harm in the tort context
12 For instance overdiagnosis and unnecessary medical tests as well as too much precaution about new approaches to cure
externality and another population that can only engage in a benign act that produces no externality. The two types of act are initially indistinguishable to the authority, but the adjudicative procedure gives rise to an evidence signal $e$ that is higher for harmful acts than for benign ones. As before the authority sanctions subjects whose acts produce an evidence signal higher than a certain cutoff value $\tilde{c}$. However now the expected sanction raises both the costs of the harmful act and that of the benign one thus chilling desirable behavior. Kaplow (2011) shows that the optimal $\tilde{c}$ that equates the (falling) marginal benefits of deterring harmful acts with the (rising) marginal costs of chilling benign acts is such that $\tilde{c}^* > \tilde{c}_{\text{neutral}}$.13

A similar model is proposed by Mungan (2011) where subjects can choose between inaction (precautionary activity) and, action and this second choice can produce no externality (desirable behavior) or a negative externality (harmful activity). The authority cannot distinguish with certainty whether the activity is harmful or benign but must rely on an evidence signal $e$ and balance the usual errors’ tradeoff. The expectation of sanctions wrongly imposed on desirable behavior induces subjects at the margin to switch over to precautionary activities. Again, Mungan (2011) shows that the optimal evidence threshold is such that $\tilde{c}^* > \tilde{c}_{\text{neutral}}$.

Judicial errors when the choice of care is continuous

In the model presented so far the defendant choice between complying and deviating is dichotomous. However other situations like torts are best described by a continuous choice of care level $x$. In the prevailing model of tort a legal standard $\bar{x}$ is set in order to determine liability by a potential injurer: the defendant avoids liability if his level of care is equal or above the standard one which is usually equated to the optimal level $x^*$. Craswell and Calfee (1986) and Shavell (1987a) introduce legal errors in this context by proposing a model where such legal standard is uncertain in the sense that defendants who choose a level of care $x$ only know that there is a probability $F(x)$ (decreasing in $x$) that they will be sanctioned so that choosing higher levels of $x$ decreases the probability to be punished. So if they choose $\bar{x} < x^*$ there is a $1 - F(\bar{x})$ probability of type-II error (the defendant is not made liable even if he took less than the efficient level of care) while if they choose $\bar{x} > x^*$ there is a $F(\bar{x})$ probability of type-I error (the defendant is made liable even if he took enough care). Assuming that also both the sanction $s$ and the opportunity cost of care $b$ are increasing functions of $x$, Craswell and Calfee (1986) show that with respect to the socially optimal level of $x$, the defendant’s choice of $x$ can be either undercomplying (the defendant chooses $\bar{x} < x^*$) or overcomplying ($\tilde{x} > x^*$). This is because, on one hand there is always a positive chance $1 - F(x)$ of acquittal and this increases the returns of taking lower levels of care. But on the other hand the expected sanction depends on the probability $F(x)$ and this can be driven down by increasing the level of care. The relative impact of these two countervailing effects on the final level of $x$ can be of either sign as it depend on various features of the legal environment, and in particular on the amount of uncertainty. Craswell and Calfee (1986) and Shavell (1987a) show that under some plausible assumptions concerning the distribution of errors14 defendants will usually take an excessive level of care. In other words, while the possibility of escaping liability when the defendant has not taken enough precaution (type-II error) has the usual adverse

---

13Intuitively it is generally optimal to raise the sanction and simultaneously raise $\tilde{c}$, holding deterrence constant. In fact the only consequence of this policy is a reduction in chilling costs.

14Shavell (2009) show that this result holds for many families of error distributions.
effect on the incentives to take precaution, the possibility of being wrongfully held liable even when one has taken enough precautions (type-I error) induces the defendant to increase the level of precautions (under some plausible conditions).

**Further effects on evidentiary standards and on type-I errors**

In addition to the literature survey above many authors have also explained the high evidence threshold usually observed in legal trials using deterrence-based arguments that point at i) biased evidence selection (Schrag and Scotchmer, 1994); ii) parties’ evidence production expenditure (Yilankaya, 2002); iii) the optimal exercise of care by parties (Demougin and Fluet, 2006); and iv) marginal deterrence (Ognedal, 2005), v) repeated offenders (Chu et al., 2000) vi) emotional costs of indignation (Nicita and Rizzolli, 2014) and so on.

Furthermore, without making reference to a specific utilitarian approach based on the deterrence rationale, a consistent number of papers simply postulate that wrongful convictions of innocents are morally repugnant and thus inherently worse than type-II errors. Arguments that justify this position can be based on i) the irreducible moral harm caused by type-I errors (McCloskey, 1965; Dworkin, 1981); on ii) the undermining effect of type-I errors on the social contract (Lee, 2011); iii) on retributivist theories that dates back at least to Immanuel Kant (2002)\(^\text{15}\). These arguments are mainly deontological and transcend the utilitarian framework although they can still be considered in our model by overweighting the impact of type-I errors on the social welfare function along the lines of Lando (2009) and Miceli (2009).

**Empirical Relevance**

The role of type-II errors has been greatly analyzed empirically and experimentally; there exists a vast literature testing Becker’s (1968) deterrence hypothesis with real data on incarceration and on the death penalty (see Levitt and Miles, 2007; Drago et al., 2009; Barbarino and Mastrobuoni, 2014); furthermore the role of punishment in experimental settings has received a great deal of attention in the last 20 years (Carpenter, 2007; Gächter et al., 2008; Chaudhuri, 2011; Boyd et al., 2010). There is also a small stream of literature testing the deterrence hypothesis in the lab Schildberg-Hörisch and Strassmair (2012); Somemans and van Dijk (2012); Khadjavi (2014a,b)

Most of this literature however ignores type-I errors and their impact on deterrence and behavior. This asymmetry is easy to understand once one considers that type-II errors (crimes that go unpunished) are far more easy to be observed and measured than type-I errors (wrongful convictions can in fact be mistaken for correct convictions. See Ehrlich, 1982). Empirical research on type-I errors has only recently taken off either comparing agreement rates of judges and juries (Spencer, 2007; Gould and Leo, 2010; Kim et al., 2013; Gould et al., 2014) or by using DNA testing introduced in the 1990s. Many innocent defendants used DNA testing to clear themselves after conviction whenever biological evidence from the crime scene had been retained. By adopting this strategy Risinger (2007) estimated the type-I error rate in capital rape-murder cases to be between 3.3% and 5% in 1982-1989. Gross and O’Brien (2008), using post-1973 US data on death sentences, estimated a type-I error frequency

\(^{15}\text{Epps (2015); Johnson (2016) offers a short and critical review of this literature}
of wrongful death sentences to be at least 2.3%. Most of this literature is concerned with measuring the magnitude of type-I errors and less with the assessment of the impact of type-I errors on general deterrence (Gould et al., 2014) with the exception of Sarel (2016). A small number of controlled lab experiments try to assess the impact of type-I errors on deterrence: Grechenig et al. (2010) first showed that both errors greatly undermine deterrence in a voluntary contribution mechanism (VCM) type of game. Rizzolli and Stanca (2012) disentangled the effects of each type of error and found that type-I errors are more detrimental to deterrence than type-II errors. Marchegiani et al. (2016 Forthcoming) found the same effect within a principal-agent setting while Markussen et al. (2014) using a VCM design, found instead the opposite effect: that type-I errors are less detrimental than type-II errors.
